VARIABLE STRUCTURE NEURAL NETWORKS FOR ADAPTIVE ROBUST CONTROL USING EVOLUTIONARY ARTIFICIAL POTENTIAL FIELDS

Hassen Mekki* ** — Mohamed Chtourou*

A novel neural network architecture, is proposed and shown to be useful in approximating the unknown nonlinearities of dynamical systems. In the variable structure neural network, the number of basis functions can be either increased or decreased with time according to specified design strategies so that the network will not overfit or underfit the data set. Based on the Gaussian radial basis function (GRBF) variable neural network, an adaptive state feedback controller is presented.

The location of the centers of the GRBFs is analyzed using a new method inspired from evolutionary artificial potential fields method combined with a pruning algorithm. Using this method we can guarantee a minimal number of neuron. It is in noted, that both the recruitment and the pruning is made by a single neuron. Consequently, the recruitment phase does not perturb the network and the pruning does not provoke an oscillation of the output response. The weights of neural network are adapted using a Lyapunov approach. Moreover, the stability of the system can be analyzed and guaranteed by introducing the supervisory controller and modified adaptation law with projection.

K e y w o r d s: variable structure neural network; radial basis functions, evolutionary artificial fields, robust adaptive control

1 INTRODUCTION

Neural network research has gained increasing attention in recent years. In fact, artificial neural networks are capable of learning and reconstructing complex nonlinear mappings and they have been widely studied by control researchers in identification analysis and the design of control systems [10, 13–15, 17]. The network size, often measured by number of hidden units in a single hidden layer network, reflects the capacity of the neural network to approximate an arbitrary function. A fundamental question is what size of the neural network is required to solve a specific problem. If the training starts with a small network, it is possible that the learning process cannot be achieved. On the other hand, if a large network is used, the learning process can be very slow and/or overfitting may occur. The approaches, which assume a priori the number of RBFs, usually lead to the problem of poor generalization. In addition, these approaches usually work offline, so they are not suitable for practical real-time applications where the online learning is required for the neural-network-based controller design. To remedy the aforementioned shortcomings, several growing RBF networks have been proposed in [8, 11, 12, 18, 21].

In using RBF networks, the basis function are placed on regular points of a square mesh, for example, covering a relevant region of space where the state is known to be contained [3, 4]. This region therefore is the network approximation region, which is in general known for a given system. The distance between the points affects the number of basis functions required to cover the region and hence determines the size of the neural network.

It seems well that if the size of the neural network input vector increases, it will have an excessive increases of the neural network size which will provoke oscillation in the output responses.

To remedy these problems, a novel neural network architecture is proposed, where the location of the centers of the GRBFs is analyzed using a new method inspired from evolutionary artificial potential field’s method.

Output tracking and stabilization of nonlinear systems has received considerable attention during last decades [4, 5, 24]. Feedback linearizing method has been widely used in this area. Although, linearizing feedback controllers are efficient in theory, they can not always be implemented in practice since they need complete knowledge about the dynamical model as well, as all its parameters. As solution, adaptive neural network controller is suggested.

In this paper, a method which concerns the fully-state linearizable or minimum phase nonlinear systems is proposed. The idea consists in designing a feedback controller constructed by a neural network. The weights of the neural network are updated such that the proposed control can track a predetermined input-output linearizing controller. Eventually, using the Lyapunov approach, it can be proved that the desired trajectory is asymptotically tracked by the output signal. As another contribution, we will show that under some structural assumptions the system drift is not necessary to construct the controller.

This paper is organized as follows. Section 2 provides a brief preliminary on fully-state linearizing control for trajectory tracking is given. In Section 3, the proposed adaptation law and the implementation of the controller...
are then presented. This is done by the use of multilayered neural networks for the identification of uncertain nonlinear functions. In Section 4, we describe a novel self-organizing RBF network that can dynamically vary its structure in real time. The proposed self-organizing RBF network is capable of adding or removing RBFs to ensure the desired approximation accuracy and at the same time to keep the appropriate network complexity. The location of the centers of the GRBFs is analyzed using a new method inspired from evolutionary artificial potential fields method. To show the obtained performances of the proposed algorithm, Section 5 presents two simulation examples. The first one deals with a based variable structural identification of a nonlinear function. The second example treats the robust adaptive control of nonlinear dynamical system.

2 LINEARIZING CONTROL

In this study, we consider an nth-order nonlinear system, with the input \( u \in \mathbb{R} \) and the output \( y \in \mathbb{R} \) described as

\[
\begin{align*}
x^{(n)} &= f(x, \dot{x}, \ldots, x^{(n-1)}) + g(x, \dot{x}, \ldots, x^{(n-1)})u, \quad y = x
\end{align*}
\]  

(1)

where \( f, g : \mathbb{R}^n \rightarrow \mathbb{R} \) are unknown nonlinear function. It will be assumed that there exist two constants \( f_{\text{max}} > 0 \) and \( g_{\text{min}} > 0 \) such that \( |f| \leq f_{\text{max}} \) and \( |g| \geq g_{\text{min}} \).

Let \( X = [x, \dot{x}, \ldots, x^{(n-1)}]^T = [x_1, x_2, \ldots, x_n]^T \in \mathbb{R}^n \) be the state vector of the system. As is well-known, if \( f(X) \) and \( g(X) \) of the system (1) are known, then the feedback linearization technique can be employed to design a desired controller. Let \( e = y_d - y \) be the error between the desired and the actual outputs. Define \( Y_d = [y_d, \dot{y}_d, \ldots, y_d^{(n-1)}]^T \) and assume that \( y_d, \dot{y}_d, \ldots, y_d^{(n-1)} \) are all bounded. Then the error vector of the system becomes \( E = Y_d - X = [e, \dot{e}, \ldots, e^{(n-1)}]^T = [e_1, e_2, \ldots, e_n]^T \). Suppose we choose a gain vector \( K = [k_0, \ldots, k_{n-1}]^T \) such that all roots of \( s^n + k_{n-1}s^{n-1} + \ldots + k_1s + k_0 = 0 \) are in the left-half complex plane. Let the feedback control law given by

\[
u^*(t) = \frac{1}{g(X)}[-f(X) + y_d^{(n)} + K^T E].
\]  

(2)

Substituting (2) into (1), we have

\[
e^{(n)} + k_{n-1}e^{(n-1)} + \ldots + k_1\dot{e} + k_0e = 0.
\]  

(3)

Consequently, from (3), we have \( e(t) \rightarrow 0 \) as \( t \rightarrow \infty \), so, \( y \rightarrow y_d \) asymptotically. However, it is noted that \( f(X) \) and \( g(X) \) of the system (1) are assumed to be unknown in this study.

3 PROPOSED ADAPTIVE CONTROLLER

One of the main drawbacks of the linearizing state feedback law is the difficulty to construct the nonlinear part, in addition to a necessary exact knowledge of the system model \( f(X) \) and \( g(X) \).

To solve this problem, we suggest using an adaptive neural network controller and a control law given by

\[
u = u_N(E, W) + u_s,
\]  

(4)

where \( u_N \) is the output of a direct adaptive neural controller (5) and \( u_s \) is a supervisory control action which is achieved only when the error of the system exceeds some bound.

\[
u_N = \sum_{i=1}^{N} w_i \varphi_i(e)
\]  

(5)

where the activation function \( \varphi(\cdot) : \mathbb{R} \rightarrow \mathbb{R} \) is a Gaussian function and \( N \) is the number of neurons in the hidden layer and \( w_i \) are the weights between the hidden and the output layer (see Fig. 1).

Throughout the paper, the following assumption is made.

ASSUMPTION 1. Let define the constraint sets \( \Omega_x \) and \( \Omega_W \) for the state \( X \) and the adjustable parameter vector \( W \) as

\[
\begin{align*}
\Omega_x &= \{ X \in \mathbb{R}^n : \|X\| \leq M_x \}, \\
\Omega_W &= \{ W \in \mathbb{R}^N : \|W\| \leq M_W \},
\end{align*}
\]

(6)

where \( M_x \) and \( M_W \) are the pre-specified parameters. Intuitively, \( \Omega_x \) is the feasible set of the state \( X \).

From equations (1) and (4), we have

\[
\begin{align*}
\dot{x}_n &= f(X) + g(X)[u_N(E, W) + u_s] = \\
f(X) + g(X)[u_N(E, W) + u_s] + g(X)u^* - g(X)u^* &= \\
f(X) + g(X)[u_N(E, W) + u_s] - f(X) + y_d^{(n)} + K^T E - g(X)u^* \quad = y_d^{(n)} + K^T E - g(X)[u^* - u_N(E, W) - u_s].
\end{align*}
\]  

(6)
This implies that
\[ e^{(n)} = -K^T E + g(X)[u^* - u_N(E, W) - u_s]. \]  
(7)

Let \( B_c = \begin{bmatrix} 0 & \vdots & 0 \end{bmatrix} \), \( A_c = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & g(X) \end{bmatrix} \).

We have
\[ \dot{E} = A_c E + B_c [u^* - u_N(E, W) - u_s]. \]

(8)

THEOREM. Consider the class of nonlinear dynamical systems described by (1) with assumption 1. Assume that the state vector \( X \) is measurable and \( y_d \) is a smooth reference trajectory to be tracked. If the control input \( u \) is designed such that in (4) with (5), and \( u_s \) is given by
\[ u_s = I^*(\text{sgn}(E^T P B_c)[|u_N(E, W)| + g_{\min}(f_{\max} + |y_d^n|) + |K^T E|]). \]
The weight vector are adjusted using the adaptive mechanism given by
\[ \dot{W} = \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} \]
if \( ||W|| < M_W \) or
\[ ||W|| = M_W \text{ and } E^T P_n g_{\min} W^T \frac{\partial u_N(E, W)}{\partial W} \geq 0, \]
\[ \dot{W} = \text{Pr}\{\gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W}\} \]
otherwise.

(9)

(10)

where the projection operator \( \text{Pr}\{\cdot\} \) is defined as \[ 24 \]
\[ \text{Pr}\{\gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W}\} = \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} - \gamma E^T P_n g_{\min} \frac{W}{||W||^2} W^T \frac{\partial u_N(E, W)}{\partial W} \]
and \( P_n \) the \( n \)th column of \( P \) (\( P \) is positive definite symmetric matrix described afterward). Then the output tracking error asymptotically converges to zero.

Proof. Consider the Lyapunov function candidate
\[ V_c = \frac{1}{2} E^T P E, \]
where \( P \) is a positive-definite symmetric matrix satisfying the Lyapunov equation
\[ A_c^T P + P A_c = -Q \]
and \( Q \) is a given positive-definite symmetric matrix. In the following, we will choose \( Q \) such that \( \lambda_{\min}(Q) > 1 \), where \( \lambda_{\min}(Q) \) denotes the minimum eigenvalue of \( Q \).

Define
\[ V_M = \frac{1}{2} \lambda_{\min}(P)(M_x - ||Y_d||_\infty)^2. \]

(13)

Note that if \( ||X|| \geq M_x \), then, from (11), we have
\[ V_c \geq \frac{1}{2} \lambda_{\min}(P)||E||^2 \geq \frac{1}{2} \lambda_{\min}(P)(||X|| - ||Y_d||)^2 \]
\[ \geq \frac{1}{2} \lambda_{\min}(P)(M_x - ||Y_d||_\infty)^2 = V_M. \]

Hence if \( V_c < V_M \), then \( ||X|| < M_x \). The time derivative of \( V_c \) along the trajectories of the closed-loop system (8) satisfies
\[ \dot{V}_c = \frac{1}{2} E^T \left( A_c^T P + P A_c \right) E + E^T P B_c [u^* - u_N(E, W) - u_s] \]
\[ = -\frac{1}{2} E^T QE + E^T P B_c [u^* - u_N(E, W) - u_s] \]
\[ \leq -\frac{1}{2} E^T QE + \frac{1}{2} E^T P B_c (|u^*| + |u_N(E, W)|) - E^T P B_c u_s. \]

Let \( P_n \) be the \( n \)th column of \( P \). We have
\[ E^T P B_c = E^T P_n g. \]

(14)

From (2) and the hypothesis \( |f| \leq f_{\max} \) and \( |g| \geq g_{\min} \) we have
\[ u^* \leq g_{\min}(f_{\max} + |y_d^n|) + |K^T E|. \]

Define the indicator function \( I^* \) by \( I^* = 1 \) if \( V_c \geq V_M \) and \( I^* = 0 \) if \( V_c < V_M \). Hence, if the supervisory controller is chosen as
\[ u_s = I^* (\text{sgn}(E^T P B_c)[|u_N(E, W)| + g_{\min}(f_{\max} + |y_d^n|) + |K^T E|] \]

(15)

where \( \text{sign} \) represent the sign function. Then, from (13) and (15), we can guarantee that \( V_c < 0 \) if \( V_c \geq V_M \).

On the other hand, in order to derive a proper adaptation law for the parameter vector \( W \in \mathbb{R}^n \), let \( W^* \) be the optimal parameter vector such that the approximation error
\[ \delta = u_N(E, W^*) - u^* \]

(16)
is minimized. Notice that from (2) the \( u^* \) is a function of time, hence so is \( W^* \).

For simplicity of analysis, we may choose \( \Omega_W \) large enough such that \( W^*(t) \in \Omega_W \) for all \( t \). By incorporating (16), (8), we can write
\[ \dot{E} = A_c E + B_c [u_N(E, W^*) - u_N(E, W) - u_s] - B_c \delta. \]

(17)

Let consider another Lyapunov function candidate, containing the error of the system and the error between the optimal parameter \( W^* \) and the actual parameter \( W \)
\[ V = \frac{1}{2} E^T P E + (2\gamma)^{-1} (W^* - W)^T (W^* - W) \]

(18)
where $\gamma$ is a positive constant determining the convergence speed. Using (17), we have

$$
\dot{V} = \frac{1}{2} E^T (A^T P + PA_e) E + E^T P B_c \left[ u_N(E, W^*) - u_N(E, W) - u_s - \delta \right] + \gamma^{-1}(W^* - W)(\dot{W}^* - \dot{W}) =
- \frac{1}{2} E^T Q E + E^T P B_c \left[ u_N(E, W^*) - u_N(E, W) - u_s - \delta \right]
+ \gamma^{-1}(W^* - W)(\dot{W}^* - \dot{W}).
$$

(19)

The Taylor expansion of $u_N(E, W)$ around $W^*$:

$$
u_N(E, W^*) - u_N(E, W) = (W^* - W)^T \frac{\partial u_N(E, W)}{\partial W} + O(W^* - W)^2,
$$

(20)

where $O(W^* - W)^2$ is a high-order term.

The equation (19) can be written as follows

$$
\dot{V} = - \frac{1}{2} E^T Q E - \gamma^{-1}(W^* - W)^T \left[ \dot{W} - \gamma E^T P B_c \frac{\partial u_N(E, W)}{\partial W} \right] - \gamma E^T P B_c \left[ \delta - O(W^* - W)^2 \right] - \gamma E^T P B_c u_s + \gamma^{-1}(W^* - W)^T \dot{W}^*.
$$

(21)

Or $E^T P B_c u_s \geq 0$ and from (14) we obtain

$$
\dot{V} \leq - \frac{1}{2} E^T Q E - \gamma^{-1}(W^* - W)^T \left[ \dot{W} - \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} \right] - \gamma E^T P_n g_{\min} \left[ \delta - O(W^* - W)^2 \right] + \gamma^{-1}(W^* - W)^T \dot{W}^*.
$$

In order to get a proper adaptation law and simultaneously guarantee $W \in \Omega_W$, a modified adaptation law with projection is proposed as

$$
\dot{W} = \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} \text{ if } ||W|| < M_W \text{ or }
||W|| = M_W \text{ and } E^T P_n g_{\min} W^T \frac{\partial u_N(E, W)}{\partial W} \geq 0,
$$

(22)

$$
\dot{W} = \text{Pr}\left\{ \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} \right\} \text{ otherwise.}
$$

(23)

where the projection operator $\text{Pr}\{\}$ is defined as in [24] by

$$
\text{Pr}\left\{ \gamma E^T P_n g_{\min} \frac{\partial u_N(E, W)}{\partial W} \right\} = \gamma E^T P_n g_{\min} \frac{W}{||W||^2} W^T \frac{\partial u_N(E, W)}{\partial W} - \gamma E^T P_n g_{\min} \frac{W}{||W||^2} W^T \frac{\partial u_N(E, W)}{\partial W}.
$$

4 VARIABLE STRUCTURE NEURAL NETWORK

There are five parameters characterizing the RBF network approximation to be determined:
- The number of RBFs $N$,
- The type of the RBF,
- The location of the center $C_{(j)}$,
- The radius in each coordinate $\sigma_{(j)}$,
- The weight vector for each output neuron $\omega_k$.

In this section, we present a novel RBF network structure that is capable of determining the number of RBFs $N$, the location of the center $C_{(j)}$ and the weight vector for each output neuron $\omega_k$ by itself. The determination of $\omega_k$ is already seen in the section 2. We first show how to determine the location of the center $C_{(j)}$. The strategy of determination of the number of RBFs needed in the proposed online identification problem will be discussed in section 3. The proposed self-organizing RBF network is capable of adding or removing RBFs to ensure the desired approximation accuracy and at the same time to keep the appropriate network complexity.

4.1 Determination of the RBFs location center

In using RBF networks, the basis function are placed on regular points of a square mesh, for example, covering a relevant region of space where the state is known to be contained [3, 4]. This region therefore is the network approximation region, which is in general known for a given system. The distance between the points affects the number of basis functions required to cover the region and hence determines the size of the neural network.

It seems well that if the size of the neural network input vector increases, it will have an excessive increases of the neural network size which will provokes oscillation in output responses.

To remedy these problems, a novel neural network architecture, is proposed, where the location of the centers of the GRBFs, is analyzed using a new method inspired from evolutionary artificial potential field method.

4.2 The Artificial Potential Field

This method is especially used in the real-time robot path planning. In the artificial potential field methods, a robot is considered as a particle under the influence of an artificial potential field $U$ whose local variations reflect e.g. the positions of obstacles and of the goal that the robot is supposed to reach [16, 20, 23]. The potential field function is defined as the sum of an attraction field that pulls the robot towards the goal and a repulsive field that repels it forms the obstacles. The movement is executed in an iterative way, in which an artificial force is induced by

$$
\vec{F}(q) = -\nabla U(q).
$$

(24)
That forces the robot to move to the direction that the potential field decreases, where \( \nabla \) is the gradient with respect to \( q \) and represents the coordinates of the robot position. The complete potential field is a superposition of contributions from obstacles, waypoint (if applicable), and the gradient of the attractive potential

\[
U(q) = \sum_{j=1}^{n_o} U^o_j(q) + \sum_{j=1}^{n_w} U^w_j(q) + U^g(q)
\]

(25)

where \( n_o \) and \( n_w \) denote the number of obstacles and waypoints, respectively, and \( U^o_j \) and \( U^w_j \) are their potential. \( U^g \) is the potential generated by the goal (navigation target).

In our approach, a neuron plays the role of the robot, the other neurons play the roles of the obstacles and the current true state of the system, is the goal point.

Different potential functions have been proposed in literature. The most commonly used attractive potential take the form \([19, 22]\):

\[
U_{\text{att}}(q) = \frac{1}{2} \beta \rho^m(q, q_{\text{goal}})
\]

(26)

where \( \beta \) is a positive scaling factor, \( \rho(q, q_{\text{goal}}) - q \) is the distance between the neuron \( q \) and the goal \( q_{\text{goal}} \), and \( m = 1 \) or \( 2 \), the attractive potential is conic in shape and the resulting attractive force has constant amplitude except at the goal, where \( U_{\text{att}} \) is singular. For \( m = 2 \), the attractive potential is parabolic in shape. The corresponding attractive force is then given by the negative gradient of the attractive potential

\[
F_{\text{att}}(q) = -\nabla U_{\text{att}}(q) = \beta \frac{(q_{\text{goal}} - q)}{\|q_{\text{goal}} - q\|}
\]

(27)

which is a constant force on the space: it does not tend to infinity with increasing distance from \( q_{\text{goal}} \). However, it is not zero at \( q_{\text{goal}} \).

One commonly used repulsive potential function takes the following form \([1]\)

\[
U_{\text{rep}}(q) = \begin{cases} 
\frac{\eta}{\rho(q, q_{\text{new}})} - \frac{1}{\rho_0} & \text{if } \rho(q, q_{\text{new}}) \leq \rho_0, \\
0 & \text{if } \rho(q, q_{\text{new}}) > \rho_0
\end{cases}
\]

(28)

where \( \eta \) is a positive scaling factor, \( \rho(q, q_{\text{new}}) \) denotes the minimal distance from the center of neuron \( q \) and the center of other neuron, \( q_{\text{new}} \) denotes the center of the nearest neuron, and \( \rho_0 \) is a positive constant denoting the distance of influence of the neuron. The corresponding repulsive force is given by

\[
F_{\text{rep}}(q) = -\nabla U_{\text{rep}}(q) = \begin{cases} 
\eta \left( \frac{1}{\rho(q, q_{\text{new}})} - \frac{1}{\rho_0} \right) \nabla \rho(q, q_{\text{new}}) & \text{if } \rho(q, q_{\text{new}}) \leq \rho_0, \\
0 & \text{if } \rho(q, q_{\text{new}}) > \rho_0
\end{cases}
\]

(29)

The total force applied to the neuron is the sum of the attractive force and the sum of the repulsive force

\[
F_{\text{total}} = F_{\text{att}} + \sum F_{\text{rep}}.
\]

(30)

This determines the motion of the neuron.

The attractive and the repulsive phenomena are given by Fig. 2.

The parameters \( \beta \), \( \eta \) and \( \rho_0 \) are chosen so that we obtain a scenario similar to the Fig. 3. We obtain concentrations of neurons in a balls of dimension \((n + m)\) centered in the desired point. By construction we obtain several layers (or orbit) of radius \( r_i \approx i \sigma \) were \( i \) is the rank of the orbit and \( \sigma \) is the width of the GRBF.

### 4.3 Determination of the number \( N \)

The proposed self-organizing RBF network is capable of adding or removing RBFs to ensure the desired approximation accuracy and at the same time to keep the appropriate network complexity.

#### 4.3.1 Adding RBFs

As the system trajectory evolves in time, the approximation error \( e \) is measured. We first check if the Euclidean norm of the approximation error \( e \) exceeds a predetermined threshold \( e_{\text{max}} \), and the period between the two adding operations is greater than the minimum response time \( T_r \). \( e_{\text{max}} \) and \( T_r \) are design parameters. If
these two conditions are satisfied, we recruit a new neuron which will be placed on a neighborhood of the last orbit. Its noted, that the recruitment is made by a single neuron. By consequence, the recruitment phase does not perturb the network.

4.3.2 Removing RBFs

The RBF removing operation is also implemented sequentially for all \( N \) coordinates. We first measure the approximation error \( e \). If the Euclidean norm of the approximation error \( e \) is smaller than \( \tau e_{\text{max}} \), where \( \tau \in (0, 1) \) is a design parameter, we remove a neuron from the last orbit. It is noted, that the pruning is also made by a single neuron, which aims at not provoking an oscillation of the output response.

4.4 Neural network adaptive control Algorithm

Choose the design parameters \( A_c, Q, f_{\text{max}}, g_{\text{min}}, e_{\text{max}}, M_x, M_w, \tau, T_r \). Initialize some GRBFs in a neighborhood of the initial condition and the weight matrix \( W \) of the initial RBF network. In each sampling period, repeat the following steps.

1) Compare the current and the desired output of the system to obtain the approximation error \( e = y - y_d \).
2) If \( e > e_{\text{max}} \) and the period between two adding operation is greater than \( T_r \), go to 3); otherwise, go to 4).
3) Add a new neuron which will be placed on a neighborhood of the last orbit. The radius of this orbit is given by: \( r_{\text{last}} = (i_{\text{last}} + 1)\sigma \); where \( i_{\text{last}} \) is the rank of the last layer.
4) If \( e \leq \tau e_{\text{max}} \), go to 5); otherwise go to 6).
5) Remove a neuron from the last orbit
6) Update the weight matrix \( W \) using (9) and (10).
7) Calculate output of a direct adaptive neural controller using (5)
8) Determination of the motion of the GRBF in the space using (30).

5 SIMULATION RESULTS

In this section, we test our proposed real-time self-organizing RBF network approximator on two examples: the first one deal with the on-line identification of a nonlinear function using the gradient method. The second example treats the real-time approximation of nonlinear dynamical system using the proposed direct adaptive robust control given in Section 3.
5.1 On-line identification of a nonlinear function

For this problem, the considered nonlinear function is described by the following equation

\[ y(x_1, x_2) = x_2 \cos(x_1) + 2 \sin(x_1). \] (31)

The aim is to seek an optimal number of RBF using the proposed algorithm, to approximate adaptively the function with small error.

Based on simulation studies, the parameters of the proposed algorithm are chosen as follows

\[ e_{\text{max}} = 0.1, \tau = 0.5, \sigma = 0.5, \rho_0 = 2\sigma, \eta = 1.5. \]

The initial number of the hidden units is chosen as \( N = 4 \).

Figure 4 shows the simulation results of the process using the proposed algorithm. Figures 4(a) and 4(b) show respectively, the evolution of \( x_1(t) \) and \( x_2(t) \). The evolutions of the desired function and its estimate are given by figs. 4(c) and 4(d) respectively. It is clear that the approximation error is so acceptable. Figure 4(e) represents the evolution of the hidden units number. It is noted that we used a minimal number of neuron on this simulation. Figure 4(f) represents the localization of the centers of the used RBFs. It is obvious that the centers are joined together all around the state \((x_1, x_2)\) to be estimated.

5.2 Neural network Adaptive control

This example illustrates a one-link rigid robotic manipulator. The dynamic equation of the one-link rigid robotic manipulator is given by [4]

\[ m l^2 \ddot{q} + d \dot{q} + m l g \cos(q) = u, \] (32)

where the link is of length \( l \) and mass \( m \), and \( q \) is the angular position with initial value \( q(0) = 0.1 \) and \( \dot{q}(0) = 0 \).

The parameters \( m, l, d \) and \( g \) are

\[ m = 1 \text{ kg}, l = 1 \text{ m}, d = 0.1 \text{ and } g = 10 \text{ m/s}^2. \]

The above dynamical equation can be written as the following state equation

\[ \dot{x}_1 = x_2, \]
\[ \dot{x}_2 = \frac{1}{ml^2} [-d x_2 - m l g \cos(x_1)] + \frac{1}{ml^2} u, \] (33)
\[ y = x_1. \]

The output of the closed-loop system has to track a desired output \( y_d \) by using the proposed control scheme. From (30), we choose \( f_{\text{max}} = 1 \) and \( g_{\text{min}} = 0.8 \).
Fig. 6. (a) – output tracking of the angular position, (b) – control input signal, (c) – neural controller, (d) – supervisory controller, (e) – Evolution of the RBF number

\[ Q = \begin{bmatrix} 1 & 2 \\ 3 & 0 \\ 0 & 3 \end{bmatrix}, \quad A_c = \begin{bmatrix} 0 & 1 \\ -1 & -2 \end{bmatrix}, \quad \text{and} \quad P = \begin{bmatrix} 4.5 & 1.5 \\ 1.5 & 1.5 \end{bmatrix}. \]

In the following simulations, the number of the hidden units is chosen as \( N = 9 \), the weights \( w(0) \) are chosen randomly in the interval \([-0.5, 0.5]\). Moreover, we choose \( M_x = 1.1 \) and \( M_W = 10 \). Figure 5 shows the simulation results of the process using the proposed algorithm. Figures 5(a) and 5(b) show the output response of the system and the corresponding control action control based on the neural adaptive state feedback controller. It is obvious that satisfactory output tracking performances have been achieved through the proposed control scheme. Figures 5(c) and 5(d) represent respectively the corresponding neural controller and the supervisory controller outputs. The evolution of the RBFs number is presented in Fig. 5(e). To test the robustness of the proposed algorithm, some disturbances are applied to the considered system. The initial conditions are chosen as in the first simulation, but only \( f_{max} \) and \( g_{min} \) are modified as \( f_{max} = 2 \) and \( g_{min} = 0.6 \).

Figures 6(a) and 6(b) show the output response of the system and the corresponding control based on the neural adaptive state feedback controller. It is well seems that the perturbations are well rejected using the proposed control scheme. Figures 6(c) and 6(d) represent respectively the corresponding neural controller and the supervisory controller outputs. Figure 6(e) represents the evolution of the hidden units number. It is clear that we used a minimal number of neuron on this simulation.

Comparing with other works \([3, 4, 6, 7]\), it is so clear that we used a minimal number of neuron while respecting the imposed performances. We can notice too, that the recruitment is made by a single neuron. By consequence, the recruitment phase does not perturb the network.

6 CONCLUSION

A direct adaptive neural control for a class of nonlinear system is presented. An important contribution in our proposed scheme is that the exact knowledge of the
system model \( f(X) \) is not necessary. The adaptation law to adjust these parameters is proposed based on the Lyapunov approach. Moreover, the stability of the system can be also analyzed and guaranteed by introducing the supervisory controller and the modified adaptation law with projection. Moreover, a novel neural network architecture, is proposed and shown to be useful in approximating the unknown nonlinearities of dynamical systems. In the variable structure neural network, the number of basis functions can be either increased or decreased with time according specified design strategies so that the network will not overfit or underfit the data set. Based on the Gaussian radial basis function (GRBF) variable neural network. The location of the centers of the GRBFs is analyzed using a new method inspired from evolutionary artificial potential fields method combined with a pruning algorithm.
